Alternative Decomposition Based Approaches for Assigning Disjunctive Tasks

Abstract

We consider a special linear assignment problem where some tasks are grouped, and in each group the tasks are 'disjunctive' (in the sense that at most one of them could be performed). We show this problem NP-hard. Then we present and compare two alternative decomposition based algorithms on randomly generated instances.

Key words: Assignment, Benders decomposition, Branch-and-Bound, heuristic, lagrangian decomposition.

1. Introduction

We consider a special linear assignment problem. An instance of this problem consists of a set $I = \{i_1, \ldots, i_m\}$ of $m$ agents, a set $J = \{j_1, \ldots, j_n\}$ of $n$ tasks, $p$ subsets $S_1, \ldots, S_p$ of $J$, and an $m \times n$-matrix $(p_{ij})$ which gives the profit of assigning task $j$ to agent $i$. The tasks grouped in each subset $S_k \subset J$ are 'disjunctive' or conflicting in the sense that at most one of them could be performed. A task can be realized by at most one agent, and an agent can perform at most one task. Now, the goal is to assign the tasks to the agents so as to maximize the total profit. Let $K = \{k_1, \ldots, k_p\}$ be the set of the indices of the groups of disjunctive tasks. The mathematical model of our problem, called assignment problem of disjunctive tasks (APDT), is

$$\max \sum_{i \in I} \sum_{j \in J} p_{ij} x_{ij}$$

$$\sum_{j \in J} x_{ij} \leq 1 \quad i \in I$$

$$\sum_{j \in S_k} \sum_{i \in I} x_{ij} \leq 1 \quad k \in K$$

$$x_{ij} \in \{0, 1\} \quad i \in I, j \in J$$

where $x_{ij}$, as usual, is a binary variable that indicates whether task $j$ is assigned to agent $i$. Constraints (2) ensure that each agent can perform at most one task, and constraints (3) specify that, in each subset $S_k \subset J$, at most one task can be performed. Problem APDT is thus an integer programming problem with $m \times n$ binary variables and $m + p$ linear inequalities. Since $x_{ij} = 0, i \in I, j \in J$, is a trivial feasible assignment, and since the objective function value is bounded from above by $\sum_{i \in I} \sum_{j \in J} p_{ij}$, problem APDT has always an optimal solution.

Note that if the subsets $S_k, k \in K$, were disjoint, or if their pairwise intersection was restricted to one task, problem APDT would be easy. However, as we shall see, the problem is NP-hard for general instances.

Claim 1 Problem APDT is NP-hard.

Proof: Set $y_j = \sum_{i \in I} x_{ij}$ and $p_{ij} = 1, i \in I, j \in J$. It follows from (3) and (4) that $y_j \in \{0, 1\}$. So, problem
APDT restricted to (1), (3) and (4) reads

$$\max \sum_{j \in J} y_j$$

$$\sum_{j \in S_k} y_j \leq 1 \quad k \in K$$

$$y_j \in \{0, 1\} \quad j \in J$$

a maximum cardinality set packing problem which is NP-hard. Thence problem APDT is at least as hard.

The problem APDT has a very interesting application since it also models a real-life practical problem, the combinatorial auction problem (CAP) (see [9]). Therefore, any algorithm for APDT should solve the CAP. Furthermore, the APDT might be interesting from theoretical as well as from algorithmic point of view (see references [1,2] for analogous extensions of the standard linear assignment problem). Nevertheless, our sole purpose here is to use it as a tool for: 1) designing two alternative (Branch-and-Bound and Benders like) algorithms; 2) comparing them from computing time point of view; 3) showing they have completely reverse behavior according to the density of the instance (which will be defined later).

In fact, the simple trick used in the proof above permits to transform APDT into a mixed binary linear program with \(m \times n\) continuous variables and only \(n\) binary ones. Let us rewrite problem APDT as follows (call R the resulting problem)

$$\max \sum_{i \in I} \sum_{j \in J} p_{ij} x_{ij}$$

$$\sum_{j \in J} x_{ij} \leq 1 \quad i \in I$$ \hspace{1cm} (5)

$$\sum_{i \in I} x_{ij} = y_j \quad j \in J$$ \hspace{1cm} (6)

$$\sum_{j \in S_k} y_j \leq 1 \quad k \in K$$ \hspace{1cm} (7)

$$x_{ij} \geq 0 \quad i \in I, j \in J$$ \hspace{1cm} (8)

$$y_j \in \{0, 1\} \quad j \in J$$ \hspace{1cm} (9)

For fixed binary \(y_j\)’s, constraints (5) and (6) become flow constraints on the bipartite graph with node set \(I \cup J\). Therefore, we can relax the integrality constraints on variables \(x_{ij}\). Furthermore, from the constraints (5) we have that \(x_{ij} \leq 1\) are always valid. Problems R and APDT are thus equivalent.

Now, consider a third problem, called P, which is problem R with constraints (6) replaced by

$$\sum_{i \in I} x_{ij} \leq y_j \quad j \in J$$

Claim 2 Problems P and R are equivalent.

Proof: Let \(F_P\) and \(F_R\) be respectively the sets of feasible solutions of problems P and R. Clearly, problem P is a weaker formulation since \(F_R \subseteq F_P\). Therefore it suffices to show that from any optimal solution of problem P we can extract an optimal solution of problem R. Assume \((x, y)\) is an optimal solution of problem P and set \(z_j = \sum_{i \in I} x_{ij}, j \in J\). Clearly \((x, z)\) is a feasible solution for problem R with the same objective function value as \((x, y)\). Therefore \((x, z)\) is optimal.

2. An heuristic for APDT

Another way to describe the relationship between the disjunctive tasks, is to define the sets \(E_j = \{k \in K \mid |S_k| \geq j\}, j \in J\). We have \(j \in S_k \iff k \in E_j\) and \(\sum_{j=1}^{|J|} |E_j| = \sum_{j=1}^n |E_j|\) (\(|\cdot|\) stands for set cardinality). For convenience, assume \(|E_j| \neq 0, j \in J\) (it is easy to deal with a task which does not belong to any group of disjunctive tasks). In fact, problem APDT consists of seeking for a maximum weight matching in the bipartite graph \((I, J)\) (the weights are the \(p_{ij}\)’s) with the additional requirement that the set \(J' \subset J\) of the vertices of the matching must satisfy \(E_i \cap E_j = \emptyset, i, j \in J'\). This observation leads to the ‘natural’ heuristic described in what follows. Obviously, this heuristic guarantees the achievement of a feasible assignment for problem APDT but not an optimal one. Set

$$d_j = \max_{i \in I} p_{ij}$$

Algorithm 1

1. Solve the set packing problem

$$\max \sum_{j \in J} d_j y_j$$

$$\sum_{j \in S_k} y_j \leq 1 \quad k \in K$$

$$y_j \in \{0, 1\} \quad j \in J$$

Let \(J' = \{j \in J \mid y_j = 1\}\).

2. Solve the maximum weight matching on the bipartite graph with node set \((I \cup J')\).
Example Consider the following instance of APDT: 
\[ m = 3, n = 5, p = 3, S_1 = \{1, 2, 5\}, S_2 = \{1, 2, 4\}, S_3 = \{2, 3, 4\} \] and the matrix of the \( p_{ij} \)'s
\[
\begin{pmatrix}
13 & 3 & 39 & 75 & 39 \\
71 & 66 & 3 & 62 & 74 \\
63 & 47 & 47 & 97 & 90 \\
\end{pmatrix}
\]
First, we have to solve the set packing problem
\[
\begin{align*}
\max & \quad 71y_1 + 66y_2 + 47y_3 + 97y_4 + 90y_5 \\
\text{s.t.} & \quad y_1 + y_2 + y_5 \leq 1 \\
& \quad y_1 + y_2 + y_4 \leq 1 \\
& \quad y_2 + y_3 + y_4 \leq 1 \\
& \quad y_1, \ y_2, \ y_3, \ y_4, \ y_5 \in \{0, 1\}
\end{align*}
\]
whose optimal solution is \( y_1 = y_2 = y_3 = 0 \) and \( y_4 = y_5 = 1 \). So \( J' = \{4, 5\} \). Solving the maximum weight matching on the bipartite graph with node set \((I, J')\) results in assigning task 4 to agent 3 and task 5 to agent 2 with a total profit of 97 + 74 = 171.

3. Benders decomposition algorithm

Benders decomposition is a natural way to tackle our mixed binary linear problem P. This method is well presented in [7] in a more general framework. So, we shall merely present the algorithm.

For fixed \( y_j \)'s, consider the problem (SP)
\[
\begin{align*}
\max & \quad \sum_{i \in I} \sum_{j \in J} p_{ij}x_{ij} \\
\text{s.t.} & \quad \sum_{j \in J} x_{ij} \leq 1 \quad i \in I \\
& \quad \sum_{i \in I} x_{ij} \leq y_j \quad j \in J \\
& \quad x_{ij} \geq 0 \quad i \in I, j \in J
\end{align*}
\]
(which can be seen as a ‘maximum profit’ flow problem on the bipartite graph with node set \((I, J)\)) whose dual problem is
\[
\begin{align*}
\min & \quad \sum_{i \in I} u_i + \sum_{j \in J} y_jv_j \\
\text{s.t.} & \quad u_i + v_j \geq p_{ij} \quad i \in I, j \in J \\
& \quad u_i, v_j \geq 0 \quad i \in I, j \in J
\end{align*}
\]
each of which having an optimal solution. Since the feasible region of problem SP is nonempty and bounded, it follows that the feasible region of its dual has no extreme rays. So we need only consider extreme points of the dual of SP.

Algorithm 2 Benders decomposition algorithm

**Input** Integers \( m, n, p \), sets \( S_1, \ldots, S_p \) and matrix \((p_{ij})\)

**Output** optimal assignment \( \pi \) and profit \( \pi \)

\[
\begin{align*}
s \leftarrow & 0 \\
\{\text{Let } \pi^{(0)} \text{ be the optimal (or approximated) solution of the set packing problem obtained by the heuristic}\}
\end{align*}
\]

**Repeat**

**Solve the problem SP**

\[
\begin{align*}
\max & \quad \sum_{i \in I} \sum_{j \in J} p_{ij}x_{ij} \\
\text{s.t.} & \quad \sum_{j \in J} x_{ij} \leq 1, \quad i \in I \\
& \quad \sum_{i \in I} x_{ij} \leq \pi^{(s)}_j, \quad j \in J \\
& \quad x_{ij} \geq 0 \quad i \in I, j \in J
\end{align*}
\]

\{Let \( \pi \) be the optimal solution, \( \pi^{(s+1)}_j, \pi^{(s+1)} \) be the optimal dual solution and \( \pi \) be the optimal function value\}

**Add to the master problem (MP)**

\[
\begin{align*}
\max & \quad z \\
\text{s.t.} & \quad \sum_{j \in S_k} y_j \leq 1 \quad k \in K \\
& \quad z - \sum_{j \in J} \pi^{(t)}_j y_j \leq \sum_{i \in I} \pi^{(t)}_i \quad t = 1, \ldots, s \\
& \quad z \geq 0 \\
& \quad y_j \in \{0, 1\} \quad j \in J
\end{align*}
\]
the cut
\[
\begin{align*}
\max & \quad z - \sum_{j \in J} \pi^{(s+1)}_j y_j \leq \sum_{i \in I} \pi^{(s+1)}_i
\end{align*}
\]

\{Let \( \pi^{(s+1)} \) be the optimal solution and \( \pi \) the corresponding objective function value\}

\[
\begin{align*}
s \leftarrow &  s + 1 \\
\text{until } & \pi = \pi
\end{align*}
\]

Example (continued) Recall that \( \pi^{(0)}_1 = \pi^{(0)}_2 = \pi^{(0)}_3 = 0 \) and \( \pi^{(0)}_4 = \pi^{(0)}_5 = 1 \) was the optimal solution of the set packing problem corresponding to the instance of this example obtained by the heuristic. Solving problem SP gives the optimal dual solution \( \pi^{(1)}_1 = 0, \pi^{(1)}_2 = 6, \pi^{(1)}_3 = 22, \pi^{(1)}_4 = 65, \pi^{(1)}_5 = 60, \pi^{(1)}_6 = 39, \pi^{(1)}_7 = 75, \pi^{(1)}_8 = 68 \) and \( \pi = 171 \). The problem MP to be solved

...
4. Lagrangian decomposition and Branch-and-Bound

It is tempting to try to reduce problem P to a flow problem, of course by adding some kind of side constraints, since problem P is NP-hard. Having this objective in mind, we go to split every variable \( y_j, j \in J \), of problem P into \(|E_j|\) copies with one special representative, noted \( y_j^{(j)} \), as we shall see. Set \( \delta_j = \min \{ k | k \in E_j \}, j \in J \). Now, let us rewrite problem P as follows (call Q the resulting problem)

\[
\begin{align*}
\max & \quad \sum_{i \in I} \sum_{j \in J} p_{ij} x_{ij} \\
& \text{s.t.} \sum_{j \in J} x_{ij} \leq 1 \quad i \in I \\
& \sum_{i \in I} x_{ij} \leq y_j^{(j)} \quad j \in J \\
& \quad \sum_{j \in S_k} y_j^{(j)} + \sum_{j \in S_k, k \neq k_j} y_j^{(j)} \leq 1 \\
& \quad y_j^{(j)} \geq 0 \quad i \in I, j \in J \\
& \quad y_j^{(j)} \in \{0, 1\} \\
& \quad \sum_{j \in S_k} y_j^{(j)} = \delta_j \quad k \in K \\
& \quad y_j^{(j)} = y_j \quad E_j, |E_j| \geq 2, k \neq \delta_j, j \in J \quad (10)
\end{align*}
\]

For each task \( j \in J \), there are \(|E_j| - 1\) ‘coupling’ constraints (10). Though problem Q is another weaker representation of problem APDT, it is easy to see that problems Q and APDT are equivalent.

It is not at all obvious, but problem Q is an integer flow problem with homologous arcs which is known to be NP-hard (see [4]). To be convinced, let us construct the corresponding network. The node set is \( I \cup J \cup K \cup \{ s_1, s_2 \} \), where \( s_1, s_2 \) are the source and sink of the network. There are \( m + n + p + 2 \) nodes altogether. The arc set is \( U = U_1 \cup U_2 \cup U_3 \cup U_4 \cup U_5 \cup \{ s_2, s_1 \} \) where

\[
\begin{align*}
U_1 &= \{(s_1, i) | i \in I\}, \\
U_2 &= \{(i, j) | i \in I, j \in J\}, \\
U_3 &= \{(k, s_2) | k \in K\}, \\
U_4 &= \{(j, \delta_j) | j \in J\} \quad (\delta_j \text{ is an element of } K) \\
U_5 &= \{(s_1, k) | k \in E_j, |E_j| \geq 2, k \neq \delta_j, j \in J\}.
\end{align*}
\]

Let us count the number of arcs. Since \(|U_1| = m, |U_2| = m \times n, |U_3| = p, |U_4| = n, |U_5| = \sum_{j=1}^n |E_j| - n = \sum_{k=1}^p |S_k| - n \) (which depends on the groups of disjunctive tasks), there are \( m \times n + m + p + \sum_{k=1}^p |S_k| + 1 \) arcs. This is a multi-graph since there are repeated arcs in \( U_5 \). Let us call \( a_u, b_u, c_u, u \in U \), respectively the lower and upper bound on the capacity of arc \( u \), and the unit cost to go over it, which are defined as follows \( a_u = 0, u \in U \),

\[
b_u = \begin{cases} 
1 & u \in U \setminus \{(s_2, s_1)\} \\
\infty & u = (s_2, s_1)
\end{cases}
\]

and

\[
c_u = \begin{cases} 
0 & u \in U \setminus U_2 \\
p_{ij} & u = (s_2, s_1)
\end{cases}
\]

Provided that \(|E_j| \geq 2\), an arc of the form \((j, \delta_j)\) in \( U_4 \) has \(|E_j| - 1\) homologous arcs in \( U_5 \) which are of the form \((s_1, k)\), \( k \in E_j, k \neq \delta_j \). The arcs are homologous in the sense that they must carry the same value of the flow (either all 0’s or all 1’s). Before going any further, let us return to our previous example.

**Example (continued)** We have \( E_1 = \{1, 2\}, E_2 = \{1, 2, 3\}, E_3 = \{3\}, E_4 = \{2, 3\}, E_5 = \{1\}, \delta_1 = \delta_2 = \delta_3 = 5, \delta_3 = 3 \) and \( \delta_4 = 2 \). Here, task 3 (and 5) belongs to only one group, so there are no coupling constraints corresponding to these two tasks, and therefore no corresponding homologous arcs in the network. Solving APDT amounts to seeking for a maximum profit integer flow \( \varphi \) in the network of figure 1 (a triple in front of each arc \( u \) gives the values \( a_u, b_u, c_u \)) with the requirements \( \varphi_{u_1} = \varphi_{u_4}, \varphi_{u_2} = \varphi_{u_5}, \varphi_{u_2} = \varphi_{u_6}, \varphi_{u_3} = \varphi_{u_7} \).

We use Branch-and-Bound (see [5]) with ’largest-upper-bound-next’ strategy to solve problem Q. At each node of the decision tree, a local upper bound is computed by solving the relaxed problem, which is a flow
problem as already shown,
\[ \max \sum_{i \in I} \sum_{j \in J} p_{ij} x_{ij} \]
\[ \sum_{j \in J} x_{ij} \leq 1 \quad i \in I \]
\[ \sum_{i \in I} x_{ij} \leq y_{j}^{\delta_j} \quad j \in J \]
\[ \sum_{j \in S_k} y_{j}^{\delta_j} + \sum_{j \in S_k, k \neq \delta_j} y_{j}^{k} \leq 1 \quad k \in K \]
\[ x_{ij} \geq 0 \quad i \in I, j \in J \]
\[ \alpha_j \leq y_{j}^{k} \leq \beta_j \quad k \in E_j, j \in J \]

where the values of \( \alpha_j, \beta_j, j \in J \), are decided by the branching procedure as we shall see, with \( 0 \leq \alpha_j \leq \beta_j \leq 1 \). At the root node we begin with \( \alpha_j = 0, \beta_j = 1, j \in J \).

The heuristic provides a first lower bound with which we begin. Then at each node, after solving the relaxed problem, we consider the restriction of the flow \( \varphi \) on the arc set \( U_2 \). If it constitutes a feasible assignment for problem APDT and improves the current lower bound, then we update.

It hardly happens that the relaxed coupling constraints (10) are satisfied while solving the relaxed problem. When it does not, we select the bundle of homologous arcs (which are then neither all 0’s nor all 1’s) for which the sum of the values of the flow through the homologous arcs is maximum. Let \( j^* \) be the label of this bundle, we compute
\[ j^* = \arg \max_{j \in J, |E_j| \geq 2} \left( \varphi(j, \delta_j) + \sum_{k \in E_j, k \neq \delta_j} \varphi(s, k) \right) \]

The current node is separated into two nodes and we set in the first \( \alpha_{j^*} = 1 \) and in the second \( \beta_{j^*} = 0 \), to enforce the satisfaction of the coupling constraints relative to task \( j^* \).

A node is fathomed either because all the coupling constraints are satisfied, or because the flow is infeasible (recall the changes in the bounds of the capacity of the homologous arcs), or because the local upper bound is not greater than the lower bound.

**Example (finished)** At the root node, we solve the maximum profit flow on the network of figure 1. The optimal profit is 210 since the flow is null on all of the edges of the bipartite subgraph \((I, J)\) but \( \varphi(i_1, j_3) = \varphi(i_2, j_5) = \varphi(i_3, j_4) = 1 \). Let us consider the relaxed constraints of the homologous arcs. We have \( \varphi_{u_1} = \varphi_{u_4} = 0, \varphi_{u_2} = \varphi_{u_5} = \varphi_{u_6} = 0, \) but \( \varphi_{u_3} = 1 \) and \( \varphi_{u_7} = 0 \). To enforce the satisfaction of the constraint \( \varphi_{u_3} = \varphi_{u_7} \), we act as in figure 2. Recall that a lower bound (171) is provided by the heuristic. So, the two children of the root node are fathomed, and the optimality of the feasible assignment obtained by the heuristic is proven.
5. Computational experience

Both of the two algorithms were coded in C (with the ‘gcc’ compiler of Linux) and run on a compatible PC with a Pentium IV (2.4 GHz) processor. We used a Network Simplex algorithm to solve problem SP (see [3]), the Out-of-Kilter algorithm to solve the relaxed problem in the BaB algorithm (see [6]), and the ‘opbdp’ software [8] to solve the master problem MP.

The algorithms were tested on a set of 45 randomly generated instances. We fixed, once for all, the number of agents \((m = 20)\) and the number of tasks \((n = 50)\). The reason of this choice (of \(n\)) is that the ‘opbdp’ software we used to solve the master problem MP slows down for larger values of \(n\). On the other hand, since it is natural that the amount of time spent by any of the two algorithms will depend on a lot of parameters (at least on \(m, n, p\), the subsets \(S_k\), the coefficients \(p_{ij}\)), it would be interesting to fix some of the parameters and compare the algorithms from the point of view of the crucial ones. Here, two parameters are important: the number \(p\) of groups of disjunctive tasks and their ‘density’. Observe that the subsets \(S_1, \ldots, S_p\) can be described by giving a binary \(p \times n\)-matrix whose rows are the incidence vectors of the subsets. The term density should then be understood as the density of this binary matrix, which is expressed in percentage as

\[
\sum_{k=1}^{p} |S_k| \div (n \times p) \times 100
\]

The coefficients \(p_{ij}\) are randomly generated in the range \([1,10]\). In the first set of experiments, we fixed \(p = 15\) and generated and run five instances for each value of the density from 5, 10, 15, 20, 25%. In the second, the density is fixed to 15% and \(p\) varies in \{5, 10, 15, 20, 25\}. The experimental results are recorded respectively in tables 1 and 2, and summarized in figures 2 and 3. In each of the two tables, the second column refers to the profit realized by the approximated solution obtained by the heuristic, while the third column gives the optimal profit. The three following columns concern the BaB algorithm and the last two, the Benders algorithm. They refer respectively to the number of coupling constraints (10), the size of the decision tree, the time (in seconds) spent by the BaB algorithm, the number of generated cuts, and the computing time of the Benders algorithm.

The heuristic seems to be very effective since it fails only four times to discover the optimal solution. In our implementation, we solved the set packing problem using ‘opbdp’, but instead, we may approximate it in order to make the heuristic polynomial time.

For fixed \(p\) (see figure 3), we notice that the BaB algorithm generates larger decision trees and, consequently, spends more computing time as the density increases, while the Benders algorithm has a complete reverse behavior. This is easily interpreted regarding the BaB algorithm. The more the density increases, the more the groups of disjunctive tasks overlap, the more the number of coupling constraints (10) increases. But the question to know why the Benders algorithm converges quickly when the density of the \(p \times n\)-matrix (which is a sub-matrix of the master problem MP) increases is rather puzzling. The integral feasible domain (call it \(D\)) of the master problem is included in the unit hypercube of \(\mathbb{R}^n\). Does the binary matrix contain much ‘more information’ when its density increases to the point where the domain \(D\) is cut deeply off? An open question?

When the density is fixed (see figure 4), the BaB algorithm continues to behave as before, the previous interpretation remaining valid. What is surprising is that the Benders algorithm seems to be insensitive to the variation of the number \(p\).

Fine tuning the two algorithms (by improving the bounding procedure, the branching strategy, using commercial software to solve the master problem, and so on), will certainly result in speeding each of them up. However, we think it cannot go to the point where the form of the observed curves overturns.

6. Conclusion

We posed a combinatorial optimisation problem and proved its NP-hardness. Then we proposed a heuristic and two exact solution procedures from alternative decompositions. The computational experience performed

Fig. 3. Summary of table 1 (mean values)

Fig. 4. Summary of table 2 (mean values)

on a set of randomly generated instances points out that the Benders algorithm should be preferred unless the number \( p \) of groups of disjunctive tasks is small enough in relation to the number of agents \( n \) and the density is sufficiently small (\( \leq 15\% \)).
