ABSTRACT

Detailed geological mapping of the Goldenville and Halifax groups in metropolitan Halifax Regional Municipality, Nova Scotia, resulted in two-fold subdivision of both groups. The Goldenville Group was divided into the metasandstone (feldspathic wacke)-dominated Taylors Head formation and the overlying, metasiltstone-dominated, Mn-rich Beaverbank formation. The Halifax Group was divided into the Cunard formation, dominated by sulphide-rich slate, and the overlying Bluestone formation, consisting of mainly metasiltstone and metasandstone. Lithogeochemical and petrological studies resulted in the characterization of the Beaverbank, Cunard, and Bluestone formations as potential acid-producing units with pyrrhotite as the main iron-sulphide mineral. The presence of acid rock drainage (ARD) is governed by bulk-rock chemical composition and mineral assemblage. To test the predictability of ARD production, a portable XRF instrument was used to obtain relatively inexpensive whole-rock and sulphur data that were used in conjunction with conventional XRF analyses and acid-base accounting tests. Results from the three methods compare favourably. Use of the portable XRF instrument facilitates a timely and cost-effective approach to predicting ARD but does not replace the legally mandated acid-base accounting procedure.

RÉSUMÉ

Une cartographie géologique détaillée des groupes de Goldenville et de Halifax dans la municipalité régionale de Halifax, en Nouvelle-Écosse, a donné lieu à deux divisions de ces deux groupes. Pour ce qui est du groupe de Goldenville, les deux formations suivantes ont été établies: la Formation de Taylors Head, composée principalement de métatufs (wacke feldspathique) et la Formation de Beaverbank sus-jacente, composée principalement de métasiltite riche en Mn. En ce qui concerne le groupe de Halifax, les deux formations que voici ont été identifiées: la Formation de Cunard, composée principalement d'ardoise riche en sulfures, et la Formation de Bluestone sus-jacente, composée surtout de métasiltite et de métatufs. Les études lithogéochimiques et pétrologiques ont permis d'établir que les Formations de Beaverbank, de Cunard et de Bluestone étaient susceptibles d'agir comme précurseurs acides, la pyrrhotite étant le principal minéral à sulfure de fer présent. La présence d'un drainage rocheux acide (DRA) est régie par la composition chimique de la roche brute et l'association minérale. Pour vérifier la possibilité d'un DRA, de concert avec des analyses traditionnelles à fluorescence X et de bilan acide-base, un appareil portatif à fluorescence X a été utilisé pour recueillir de manière relativement économique des données sur la roche brute et les sulfures. Les résultats obtenus par les trois méthodes se comparent bien. L'utilisation d'un appareil à fluorescence X portatif permet de prédire de manière économique et rapidement la possibilité du DRA, mais cette technique ne saurait se substituer à l'analyse du bilan acide-base prévue par la réglementation.

[Traduit par la redaction]

INTRODUCTION

A detailed bedrock mapping and sampling program combined with petrographic and stratigraphic analysis was undertaken in the metropolitan portion of the Halifax Regional

Municipality (HRM) as part of the much larger southern Nova Scotia Meguma terrane mapping program (Fig. 1) (White *et al.* 2008; White 2010a). The purpose of the mapping program is to better characterize the stratigraphy, economic potential, and tectonic evolution of the Cambrian to Ordovician Golden-

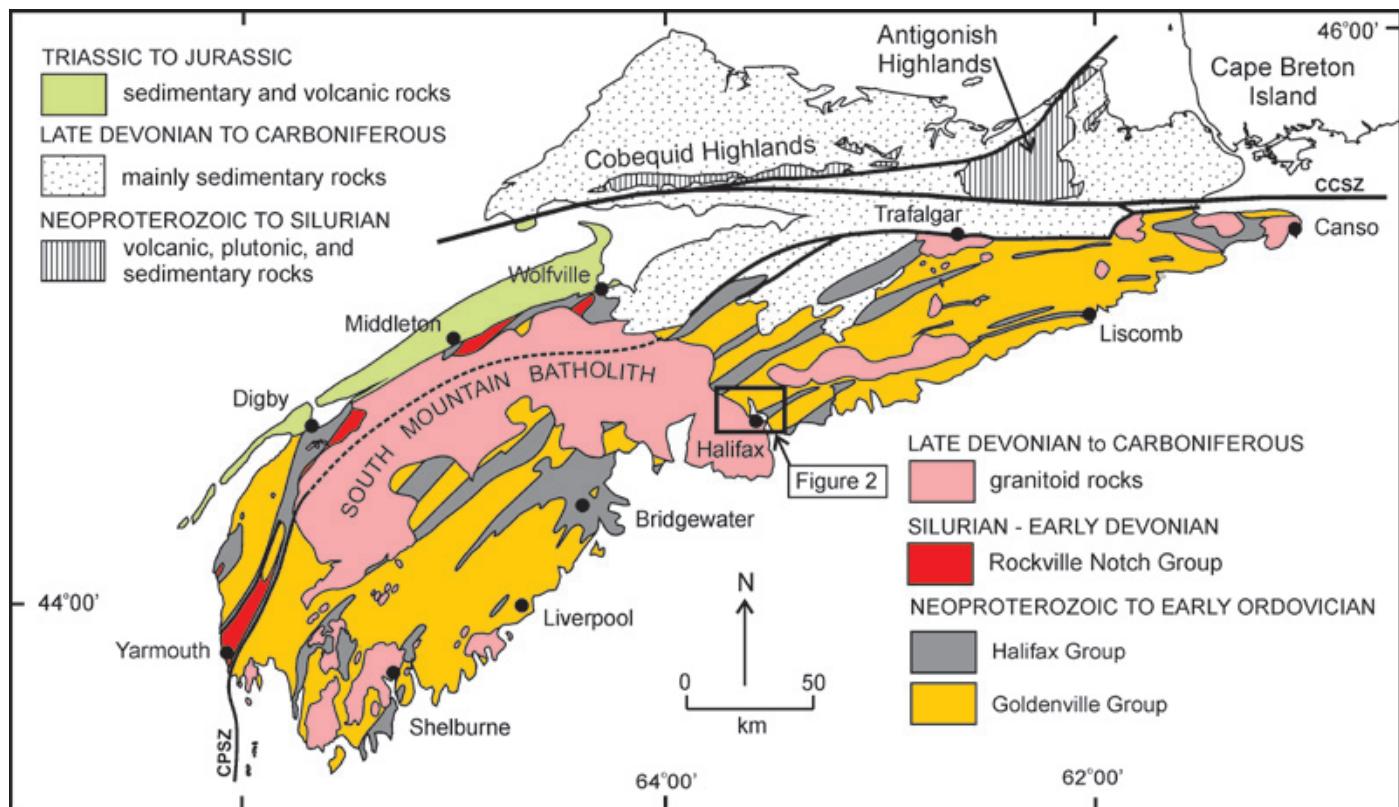

Fig. 1. Simplified geological map of the Meguma terrane of southern Nova Scotia, showing the distribution of the Goldenville and Halifax groups and other major units. The area of study is shown in the box. Abbreviations: CCSZ = Cobequid-Chedabucto shear zone; CPSZ = Chebogue Point shear zone.

ville and Halifax groups in southern Nova Scotia (e.g., White 2010a; White and Barr 2010). However, an important outcome from the mapping is the identification of units within HRM and elsewhere in the Goldenville and Halifax groups that have potential acid-generating hazards (e.g., Lewis *et al.* 1998). The production of acid and hence acid rock drainage (ARD) results from the oxidation of naturally occurring sulphide minerals in the rocks, and is a major issue facing development in the metropolitan portion of HRM. The environmental impacts associated with exposed or disturbed sulphide-rich rocks during routine construction activity (i.e., not related to metal or coal mining) are not unique to HRM and have been documented in many parts of the world (e.g., Piispanen and Nykyri, 1997; Morin *et al.* 2003; Peng *et al.* 2005; Schoeffer and Clawson 1996; Kwong *et al.* 2009).

Acid rock drainage is not only detrimental for fish and other aquatic species but also causes excessive premature corrosion of concrete and metal infrastructure. For these reasons many construction companies, geotechnical consulting groups, and public work agencies need to know areas in the city where ARD may be an issue in infrastructure construction projects. With the identification of sulphide-rich geological formations in HRM, the potential for ARD can be better understood, and as a result, the onset of acid drainage can be more effectively avoided.

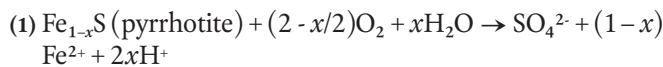

To predict the acid generating potential from any geologic formation requires the characterization of the presence and quantity of both acid-forming minerals and neutralizing minerals in the geologic materials to be unearthed during construction operations. Although a variety of laboratory-based acid-base accounting (ABA) tests are available to determine the potential for generating ARD content, here we employ the static British Columbia Research Initial Test (BC-RIT) method as recommended by the Nova Scotia Environment Act (1995). With the results from this test, combined with a detailed geological map, whole rock lithogeochemistry, and petrography, we can now accurately assess the acid-forming capability of formations which can be used for environmental management and subsequent mitigation of ARD in HRM. The purpose of this paper is to quantify the ARD-generating potential of rocks in the metropolitan portion of HRM.

ACID ROCK DRAINAGE

Acid rock drainage, also referred to as acid mine drainage (AMD), is a naturally occurring phenomenon that results when sulphide minerals in a rock are oxidized as a result of exposure to oxygen and water. In the absence of neutralizing material (e.g., limestone or dolomite) this oxidation causes the chemical

breakdown of the sulphide minerals which releases sulphuric acid, iron and other metals, and sulphate into the receiving environment, typically a stream, river, or lake.

In HRM, pyrrhotite and pyrite are the primary concerns with regard to ARD, with the oxidation rate of pyrrhotite being much faster than pyrite (Fox *et al.* 1997). The oxidation of pyrrhotite and pyrite is complex and involves a series of multiple reactions but simplified equations can be written as follows:

Other minerals such as arsenopyrite, chalcopyrite, sphalerite, galena, and magnetite are commonly overlooked as potential candidates for ARD but they can also provide additional input to acid generation through the oxidation of Fe^{2+} and hydrolysis of Fe^{3+} (Moncur *et al.* 2009). In addition, crystal structure plays an important role in the generation of ARD. For example, the monoclinic (vs. hexagonal) form of pyrrhotite has been shown to readily weather and initiate acid production (Robinson 1996).

Waterways affected by ARD can be characterized by their acidity, high sulphate and metal content in their waters, and the metallic content of their sediments (e.g., Grande *et al.* 2005). Often the aesthetic quality of a waterway is reduced by the presence of a red iron hydroxide precipitate that commonly lines the bottom sediment of the receiving waters. Depending on the pH of the water, the rate of oxidation is greatly accelerated by a variety of bacteria (e.g., *Thiobacillus thiooxidans* and *Ferrobacillus ferrooxidans* — pH between 4.5 and 3.5; *Thiobacillus ferrooxidans* — pH below 3.5) (U.S. Environmental Protection Agency 1994; Eba Engineering Consultants Ltd. 2004; Blowes *et al.* 2005). In addition to loss of aquatic life, as well as the loss of potable and industrial water resources, ARD has been responsible for damage to engineered infrastructure such as concrete structures, buried transmission lines, culverts, bridges, and metal pipes (Earle and Callagnah 1998). Acid rock drainage, once it appears, is virtually impossible to reverse and with the current technology, its treatment can cost millions of dollars and go on for centuries (Feasby and Tremblay 1995; Jennings *et al.* 2008).

In addition to the acid contribution to surface waters, ARD may cause trace metals such as aluminum, arsenic, cadmium, copper, manganese, and zinc to leach from rocks and these metals can contribute to the environmental damage, and in some cases is of greater concern than the acidity.

History of ARD in the Halifax Group

Acid rock drainage issues in Nova Scotia, in particular in the Halifax Group, were broadly researched in the late 1980s and 1990s (e.g., Pasava *et al.* 1995; Feetham *et al.* 1997; Fox *et al.* 1997; Zentilli and Fox 1997, and references within) but have seen limited research since that time. One of the earliest and

most extensively studied sites associated with ARD in HRM involved the construction and subsequent expansion(s) of the Robert Stanfield International Airport (previously referred to as the Halifax International Airport). Here a direct correlation was demonstrated between construction activity in the Halifax Group and significant fish kills in the nearby Shubenacadie River between 1960 and 1976 (Pasava *et al.* 1995; Worran 1987). Remediation and treatment costs have averaged one million dollars annually at the airport, and treatment of surface waters continues (Hicks 2003).

Construction on Highway 107 east of Dartmouth near West Petpeswick Lake during the late 1980s exposed a continuous section of Halifax Group slate which resulted in the production of ARD and the degradation of water quality and aquatic habitat. Subsequently, the acid-producing outcrop was capped with shotcrete and a small treatment facility was constructed (Fox *et al.* 1997). Other historic ARD issues that have arisen in HRM and elsewhere in Nova Scotia also were outlined in Fox *et al.* (1997).

These incidents led the Nova Scotia Department of Environment to instate the “Sulphide Bearing Material Disposal Regulations” which require testing for ARD prior to ground disturbance (Nova Scotia Environment Act 1995). However, within HRM evidence suggests that current development in Fairview, Hammonds Plains, and Middle Sackville continues to have ARD problems. The local residents in these areas who are on well-water have water softeners and filters to combat the resulting rusty stain on fixtures, discoloured laundry, and sulphur odour (Goodwin 2004). In addition, past and on-going infrastructure development such as the interchange of highways 102 and 103 as well as road building and the development of retail commercial sites in the Bayers Lake Industrial Park continue to be sources of natural ARD and acidification of local lakes (Kerekes *et al.*, 1984; Rajaratnam 2009). More recently, construction was halted during the building of the new Dartmouth bus terminal and Bayers Lake underpass as pyritic slate was encountered on these sites, dramatically increasing project costs (Talpin 2011a, b; Stephenson 2011).

GEOLOGICAL SETTING

The first step when evaluating the acid generating potential of bedrock is to understand the geological history of the area and describe the geology and mineralogy of rock formations in detail (Coastech Research Inc 1991; U.S. Environmental Protection Agency 1994; Price 2005, 2009; Jennings *et al.* 2008).

The earliest geological study in the Halifax area was undertaken by Faribault (1907, 1908) who divided the area into an older “Quartzite Division” and younger “Slate Division” intruded by coarse-grained granite. Faribault (1907) recognized the rusty character of the “Slate Division” and described the unit as highly ferruginous and altered with metamorphic minerals close to the granite contact. The area was next mapped by MacDonald and Horne (1987) but they focused primarily on the igneous units and compiled data from the earlier work

of Faribault (1908) for the metasedimentary units. Following current practice, they assigned the “Quartzite” and “Slate” divisions to the Cambrian-Ordovician Goldenville and Halifax formations, respectively.

Recent 1:10 000-scale mapping in HRM (White *et al.* 2008) was undertaken to update the old geological map of Faribault (1908). As a result, new formations were recognized and the Goldenville and Halifax formations were elevated to ‘group’ status. The older unit, the Goldenville Group, occurs in the northern and eastern parts of HRM (Fig. 2). It is divided into two formations: Taylors Head and Beaverbank (White *et al.* 2008; White 2010a, b). The Taylors Head formation consists of grey, thickly bedded and weakly cleaved, metasandstone interbedded with minor green to grey, cleaved metasiltstone, and rare black to rusty slate. Calc-silicate nodules and pyrite cubes are locally common. The contact with the overlying Beaverbank formation is conformable and marked by a decrease in thickly bedded metasandstone over tens of meters. The Beaverbank formation consists of grey to black, cleaved metasiltstone interbedded with minor thin, light grey metasandstone and black graphitic slate. Thin brown to black manganese-rich limestone beds and nodules are common. Close to the contact with granite of the South Mountain Batholith these manganese-rich limestone beds and nodules become garnet (spessartine)-rich coticules.

The overlying Halifax Group is subdivided into the Cunard and Bluestone formations (White *et al.* 2008). In the Halifax area, the Cunard formation conformably overlies the Beaverbank formation of the Goldenville Group and is characterized by black, commonly rusty on weathered surfaces, graphitic slate and metasiltstone interbedded with 10 to 30 cm thick, cross-laminated fine-grained metasandstone. This formation typically contains abundant pyrrhotite and pyrite, with lesser amounts of chalcopyrite, galena, sphalerite, and arsenopyrite (e.g., Fox *et al.* 1997; Haysom *et al.* 1997; Betts-Robertson 1998; Clarke *et al.* 2009).

The conformably overlying Bluestone formation consists of grey thinly bedded metasiltstone and slate, minor metasandstone and calcareous nodules (Jamieson *et al.* 2005a, b, 2011; White *et al.* 2008) and has recently been subdivided into several informal members (Jamieson *et al.* 2011). In contrast to metasandstone in the underlying Cunard formation, the metasandstone lacks prominent cross-laminations. The Bluestone formation generally lacks obvious sulphide minerals.

The Goldenville and Halifax groups were regionally metamorphosed (greenschist facies) and deformed into northeast-striking, upright, tight to open folds (Fig. 1, 2) with a well developed axial planar cleavage during the ca. 406–388 Ma Neoacadian Orogeny (van Staal 2007; Moran *et al.* 2007; White *et al.* 2008; White 2010a).

The ca. 380–373 Ma peraluminous South Mountain Batholith (SMB) intruded the Goldenville and Halifax groups and produced a narrow (up to 2 km wide), well developed contact metamorphic aureole that is superimposed on regional greenschist facies mineral assemblages and textures (Jamieson *et al.* 2005a, b, 2011; White *et al.* 2008) (Fig. 2). A major northwest-

striking shear zone is present in the contact aureole adjacent to the northeastern margin of the South Mountain Batholith (Fig. 2) and was active during intrusion (Culshaw and Bhattacharjee 2001; White *et al.* 2008).

Within the northeastern margin of the SMB, a narrow (0.5 to 1 km wide) northwest-trending zone of grey, medium grained, equigranular granodiorite with minor alkali feldspar megacrysts is recognized and herein termed the Quarry Lake granodiorite. Locally at the contact with the country rocks this unit contains abundant metasedimentary xenoliths. Farther southwest into the batholith several plutonic units are defined (Sandy Lake and Harrietsfield monzogranites, and Halifax Peninsula leucomonzogranite) which range from fine- to coarse-grained to megacrystic monzogranite to leucomonzogranite (MacDonald and Horne 1987; MacDonald 2001). All these units are intruded by the late-stage medium-grained two-mica Tantallon leucomonzogranite (Fig. 2).

METHODOLOGY

Field mapping (1:10 000-scale) was performed during the summers from 2007 to 2010 and included a comprehensive and detailed sampling program. A total of 239 samples from the stratified units and 21 samples from granitoid outcrops in the South Mountain Batholith were collected for petrographic analysis. A total of 76 psammic and 32 pelitic lithologies were thin-sectioned in order to obtain detailed information on mineralogy and grade of metamorphism. An additional 21 thin sections from the South Mountain Batholith were studied to document the mineralogy in the granitoid units. Twenty-eight samples were selected for polished thin sections and whole-rock geochemistry representing each lithology in the Goldenville and Halifax groups.

Magnetic susceptibility data were collected on each sample using a handheld KT-9 Kappameter. The KT-9 uses a 10 kHz LC oscillator and an inductive coil and automatically displays the true measured susceptibility of the sample in dimensionless, System International (SI) units. The maximum sensitivity of the KT-9 is 1×10^{-5} SI units. In this study, all measurements were recorded to 1×10^{-3} SI units.

To determine the background ARD potential, samples were chosen on the basis that they represented the typical lithology at any one outcrop and did not contain abundant visible sulphide mineralization or weathering features. This approach is in contrast to previous ARD studies in HRM (i.e., Fox *et al.* 1997) that specifically targeted sulphide-bearing lithologies. Samples were pre-crushed to <180 microns using a tungsten-carbide mill and major, trace, rare earth element, and total sulphur and carbon analysis were done by ICP-MS at Acme Analytical Laboratories (Vancouver) Ltd. Major oxides and several minor elements were analysed by ICP-emission spectrometry following a lithium metaborate/tetraborate fusion and dilute nitric digestion. Trace elements were determined by ICP mass spectrometry following a lithium metaborate/tetraborate fusion and nitric acid digestion. Loss on ignition

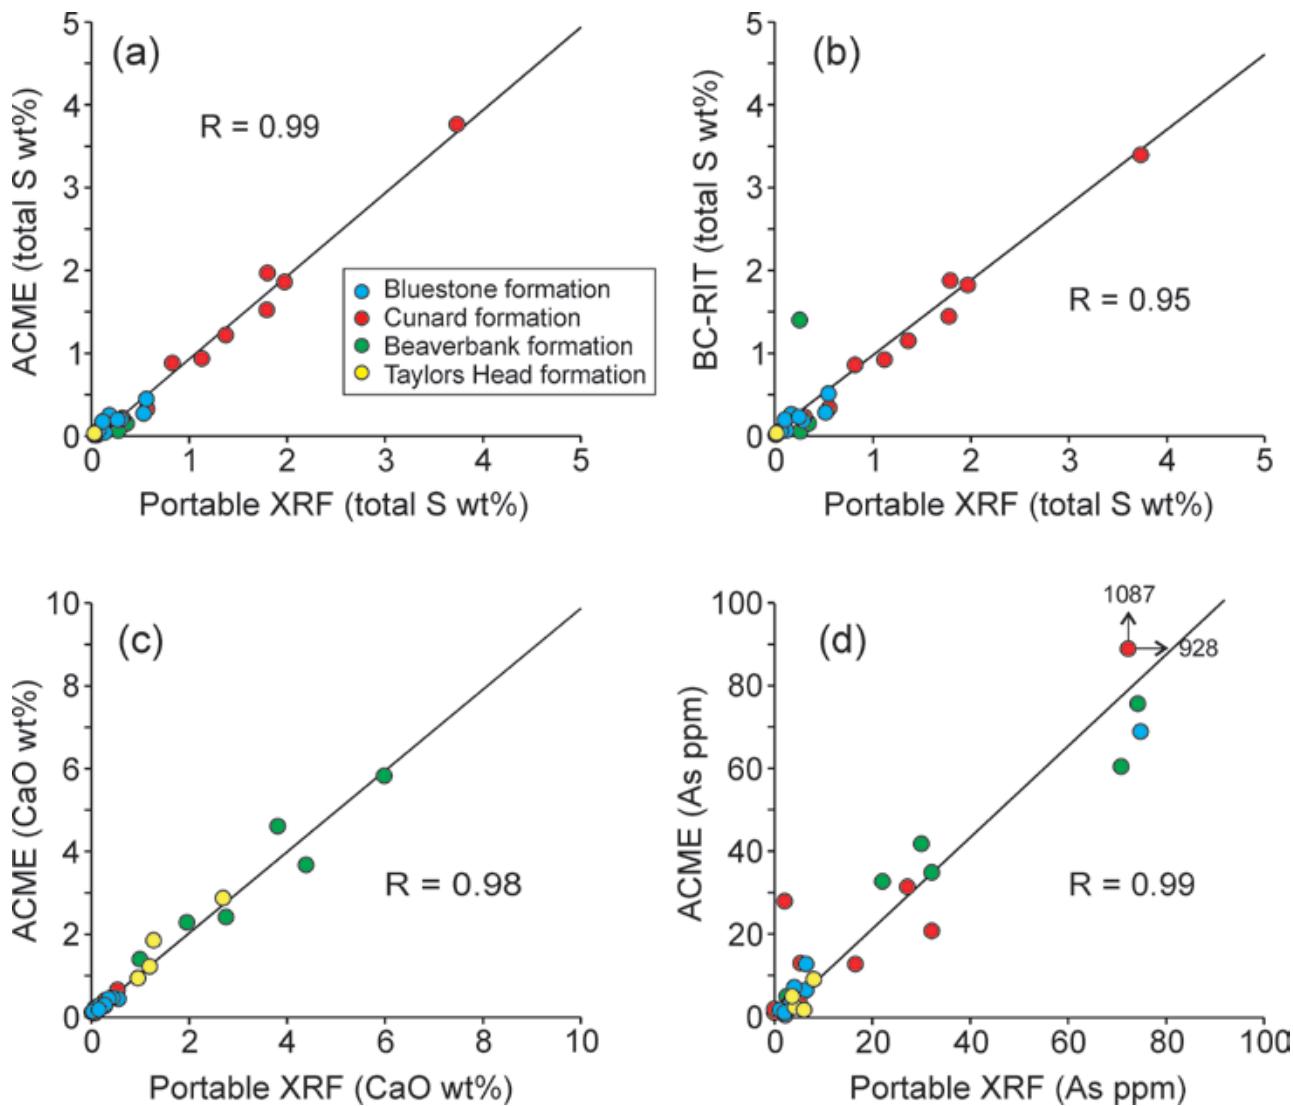

Fig. 3. Selected whole rock results using the portable XRF compared with the ACME and BC-RIT results on the sample samples. (a) Plot of total S (wt.%); portable XRF against ACME. (b) Plot of total S (wt.%); portable XRF against BC-RIT. (c) Plot of CaO (wt.%); portable XRF against ACME. (d) Plot of As (ppm); portable XRF against ACME.

(LOI) is by weight difference after ignition at 1000 °C. Four samples from the Taylors Head formation, 6 from the Beaverbank formation, 10 from the Cunard formation, and 8 from the Bluestone formation were analyzed (Table 1a, b).

In Nova Scotia, the Sulphide Bearing Material Disposal Regulations (Section 66 of the Nova Scotia Environment Act 1995) require that all samples submitted for ARD analysis should use the static British Columbia Research Initial Test (BC-RIT) and rocks having a sulphide sulphur content equal to or greater than 0.4% (12.51 kg H₂S₀₄/tonne) must be considered as hazardous ARD material. A total of 23 bedrock samples were submitted to the Minerals Engineering Centre (MEC) at Dalhousie University, Halifax, Nova Scotia, for processing and analysis using the BC-RIT method (Table 2). Each sample was analyzed by MEC for total sulphur (LECO furnace), sulphide sulphur (after determining sulphate sulphur by hydrochloric acid diges-

tion, precipitation of the sulphate using barium chloride and gravimetric finish to yield the sulphate sulphur) and for its acid producing/consumption ability using the BC-RIT method (Duncan and Bruynesteyn 1979).

In addition, all 260 samples were analyzed using a portable X-5000 XRF instrument (hereafter termed portable XRF) manufactured by Innov-X which was acquired recently by the Nova Scotia Department of Natural Resources. It uses a 10W tantalum anode light-element X-ray tube with a resolution of < 165eV. The beam is approximate 8 mm in diameter and measures 25+ transitions metals including selected rare earth elements. Samples were analyzed using the Soil 3 Beam mode with 60 second counts on each beam; however, this mode does not measure elements lighter than Na (e.g., Si, Al, and Mg).

Traverses across rock slabs, greater than 1 cm thick, were averaged (3–5 spots on fine-grained samples and 5–10 spots

on coarsergrained samples). The samples represent psammitic, pelitic, and calc-silicate rocks in all the formations in the Goldenville and Halifax groups, arranged in stratigraphic order, and include 139 from the Taylors Head formation; 34 from the Beaverbank formation, 39 from the Cunard formation, and 27 from the Bluestone formation. In addition, 21 samples from the South Mountain Batholith were analyzed. Rock type, UTM coordinates, and major and trace data are summarized in Appendices A–E.

Quality assurance and quality control

The portable X-5000 XRF provides rapid and simultaneous analyses of several elements with minimal sample preparation. To assess the reliability of analyses using the portable XRF the results are compared with the ACME results on the same samples. In addition, two internal reference samples (metasandstone and slate from the Goldenville and Halifax groups, respectively) were routinely analyzed to evaluate the portable XRF's performance. This check aids in estimation of the precision and accuracy and hence ensures meaningful interpretation of the data. Scatter plots for selected elements (S, Ca, and As) from ACME and the portable XRF results were constructed and compared to the total S analyzed by BC-RIT (Fig. 3). Correlation coefficients (r -values) on each pair were also calculated. The results show excellent reproducibility ($r \geq 0.95$). Comparing the results from ACME to the portable XRF data yielded correlation coefficients that range from 0.88 to 0.98 for K_2O , TiO_2 , MnO , $Fe_2O_3^T$, Ba, Cu, Nb, Pb, Rb, Sr, V, Y, Zn, and Zr pairs (not shown). There is no significant discrepancy in the data between the ACME and portable XRF and hence the portable XRF results can be used with a significant degree of confidence.

PETROGRAPHY

Goldenville and Halifax groups

In rocks of the Goldenville and Halifax groups away from the contact metamorphic effects of the South Mountain Batholith in the HRM area, regional greenschist facies (chlorite zone) metamorphic minerals and textures are preserved. Here the original clay-sized material in the slate as well as the matrix in metasandstone and metasiltstone has been recrystallized to a mixture of very fine-grained sericite, epidote, and chlorite. Quartz is the most abundant detrital component in the metasandstone, with lesser amounts of feldspar and minor or no lithic fragments (Fig. 4). Most feldspar grains are subrounded and consist of albitic plagioclase. It is rarely twinned and partially altered to sericite, epidote, or calcite. Potassium feldspar is rare. The metasandstone has between 18 and 38% matrix and is classified (using the system of Boggs, 2001, shown in Fig. 4a) as feldspathic wacke (Fig. 4b). Detrital muscovite is present in many samples and ranges in abundance up to 5%.

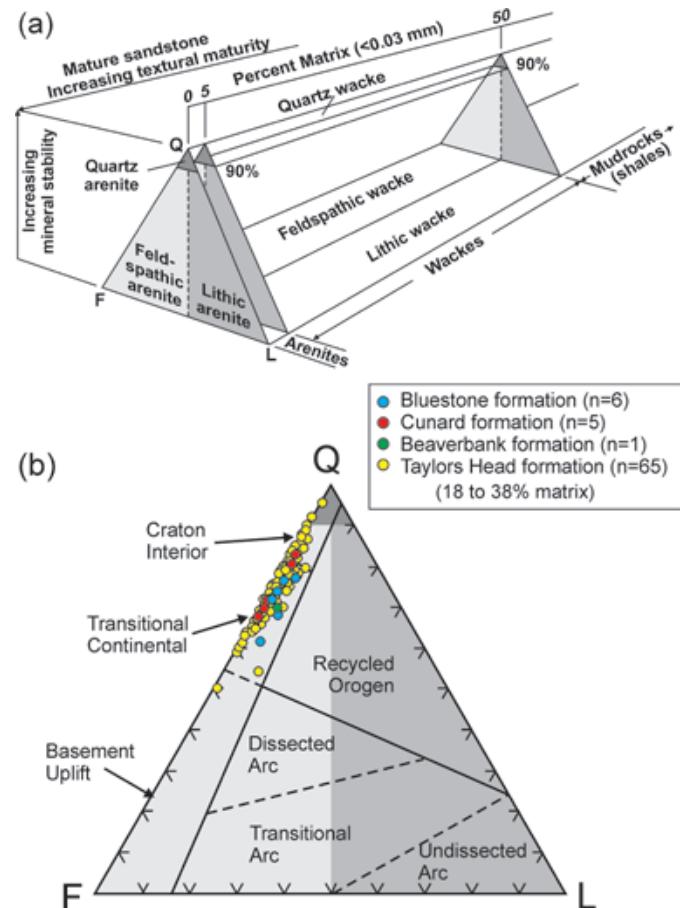

Fig. 4. (a) Classification of sandstone based on modal quartz (Q), feldspar (F), lithic fragments (L), and proportion of matrix, after Boggs (2001). (b) Classification and provenance for samples from the Goldenville and Halifax groups with <5% and <50% matrix. Shaded classification fields from (a) are shown on (b). Provenance fields are after Dickinson *et al.* (1983). About 500 to 1000 points were counted in each thin section, using a modified version of the Gazzi-Dickinson method, which includes counting grains where they form part of a lithic fragment to eliminate apparent variations in the composition of samples resulting only from differences in grain size (Ingersoll *et al.*, 1984).

Trace amounts of zircon, titanite, and tourmaline also occur. Lithic fragments are rare and are dominantly quartzite.

Calcite ($CaCO_3$), and to a lesser degree dolomite [$Ca, Mg(CO_3)_2$], occur in nodules and as minor cement in metasandstone of the Taylors Head and Bluestone formations. Calcite nodules and laminations also occur within the slate of the Beaverbank and Bluestone formations, and rhodochrosite ($MnCO_3$) has been documented in units equivalent to the Beaverbank formation (O'Beirne-Ryan 1996). Ankerite [$Ca(Fe, Mg, Mn)(CO_3)_2$] is not common but has been noted in metasandstone units within gold districts of the Goldenville Group (MacDonald 1998).

Notes: Abbreviations: SO = stratigraphic order from oldest (1) to youngest (2); APP = acid producing potential; ACA = acid consuming ability.

Magnetite and minor ilmenite are the main magnetic minerals in the metasandstone and metasiltstone beds (King 1997; Pelley 2007). They form small (0.1–0.2 mm), inclusion-rich to inclusion poor, euhedral crystals in the matrix and are metamorphic in origin; however, the more magnetic beds contain magnetite up to 2 mm in diameter, which is likely partly detrital in origin (Pelley 2007).

Cubic pyrite (1 to 2 cm in diameter) is typically rare in metasandstone of the Taylors Head formation but more abundant in the slaty rocks and metasandstone of the Cunard formation and locally is present in the Bluestone formation at lower metamorphic grades. Based on petrographic evidence the pyrite predates the regional foliation (e.g., Hicks 1996).

Pyrrhotite is not common in metasandstone beds in the Taylors Head formation but does occur locally with magnetite in the minor interbedded metasiltstone and slate. In the Beaverbank formation pyrrhotite typically occurs in the cores of spessartine garnet grains (e.g., Fox *et al.* 1997; White 2010a). Pyrrhotite, along with pyrite, is common in the Cunard for-

mation (e.g., Pasava *et al.* 1995) and locally present in the Bluestone formation. It can occur as relatively inclusion-free porphyroblasts but is typically inclusion-rich, flattened parallel to foliation, and elongate parallel to the intersection lineation and regional fold axis, indicating it grew during regional chlorite-grade metamorphism that was synchronous with regional deformation.

As metamorphic grade increases toward the contact with the South Mountain Batholith, the matrix minerals in the metasandstone beds are comprised of coarser grained white mica and decussate biotite and ultimately poikiloblastic cordierite at the contact. In these less aluminous metasandstone beds, andalusite and sillimanite are rare. In the pelitic units of the Taylors Head and Beaverbank formations the matrix material also becomes coarser grained and, like in the metasandstone, decussate biotite appears. Closer to the contact with the South Mountain Batholith, biotite content increases and ovoid cordierite appears; it has typically been weathered out leaving tiny voids in the rock. Plagioclase compositions become in-

creasingly Ca-rich with higher An contents (up to An₅₀) at the contact with the South Mountain Batholith (Mahoney 1996; White 2003; Clarke *et al.* 2009).

Jamieson *et al.* (2005 a, b) documented a change in the opaque mineralogy with increasing metamorphic grade where rutile and pyrite in the outer aureole are replaced by ilmenite and pyrrhotite closer to the contact. As noted by Clarke *et al.* (2009), pyrrhotite is the dominant sulphide in the contact aureole adjacent to the SMB, forming up to 15 modal % in some layers in the Halifax Group (Betts-Robertson 1998). Like in the lower grade metamorphic rocks, pyrrhotite remains flattened and elongate parallel to the relict foliation and intersection lineation. The pyrrhotite is typically anhedral and contains abundant inclusions of quartz, sheet silicates, Fe-Ti oxides, and other sulphide minerals that define inclusion trails parallel to the relict foliation in the matrix (i.e., Fox *et al.* 1997; Clarke *et al.* 2009). In contrast, pyrrhotite in the metasandstone beds of the Cunard formation is cubic (up to 1 cm in diameter) because it has pseudomorphed pyrite (Clarke *et al.* 2009).

In the shear zone at the contact between the SMB and country rocks, the intersection lineation becomes steeper and forms a mineral lineation defined by elongate quartz+biotite ± cordierite aggregates and elongate calc-silicate nodules in the metasandstone or boudinaged andalusite and elongate pyrrhotite in the pelitic rocks (Culshaw and Bhatnagar 2001; White *et al.* 2008). In contrast to the Taylors Head formation, the main magnetic mineral is pyrrhotite in the Beaverbank, Cunard, and Bluestone formations. Other minor sulphide minerals associated with pyrrhotite, typically as inclusions, include chalcopyrite, sphalerite, arsenopyrite, and galena. Although pyrrhotite is the dominant sulphide in some layers (Fox *et al.* 1997; Clarke *et al.* 2009), no samples collected in the study contain over 5 modal % total sulphide minerals.

South Mountain Batholith

The Quarry Lake granodiorite (Fig. 2) is medium- to coarse-grained, equigranular to megacrystic, with alkali feldspar and less abundant plagioclase megacrysts. It has abundant metasedimentary xenoliths of the Goldenville and Halifax groups. Quartz forms anhedral to subhedral grains in the groundmass but in places forms subhedral megacrysts. Plagioclase is typically in the groundmass as subhedral crystals displaying normal to oscillatory zoning, and ranging in composition from An 5–35, whereas alkali feldspar occurs as euhedral perthitic megacrysts (e.g., MacDonald 2001). Biotite is mainly subhedral to euhedral in the groundmass and forms up to 25 modal percent. Muscovite, cordierite, and garnet occur in trace amounts. The monzogranite and leucomonzogranite units to the southwest (Fig. 1) display textures similar to the granodiorite but contain more muscovite and cordierite and less biotite (MacDonald 2001).

Pyrrhotite and chalcopyrite are the main sulphide minerals in the Quarry Lake granodiorite, together with trace amounts of sphalerite, galena, arsenopyrite, and molybdenite which typically occur as inclusions in the pyrrhotite (e.g., Clarke *et al.*

2009). Although the pyrrhotite may retain a similar flattened morphology as in the adjacent country rock, it is inclusion-free, small (<2 mm in size), and in some samples appears to be interstitial. The overall modal abundance of sulphide minerals in the batholith is less than 2%, considerably less than in the adjacent country rocks but can be several volume % of the granite at the contact (Clarke *et al.* 2009). No sample of granitoid rock collected during the present study contains over 1% sulphide minerals.

A detailed description of sulphide mineral textures and chemistry in the contact aureole and adjacent granitoid rocks of the South Mountain Batholith was provided by Clarke *et al.* (2009).

RESULTS AND DISCUSSION

Lithogeochemistry

Major element oxide and trace element data can provide useful information on ARD prediction. Because the ARD behaviour of a rock is depended on its mineral assemblage, the effects of changes in mineralogical composition on acid-rock generation and buffering reactions must be considered when predicting ARD. Because the portable XRF does not measure elements lighter than Na, data from ACME is used for SiO₂, Al₂O₃, K₂O, Na₂O, and Fe₂O₃^T plots (Table 1a, Fig. 5).

Variations in SiO₂ content and SiO₂/Al₂O₃ ratio can be linked to the relative proportions of quartz, feldspar, and matrix minerals in the samples. White and Barr (2010) demonstrated this relationship for metasedimentary rocks in the Goldenville and Halifax groups in southwestern Nova Scotia. In the present study, petrographic data also were compared to their chemical compositions (Table 1a) and the results indicate that the boundary between sandstone and siltstone/mudstone is at 65% wt. % SiO₂ with a corresponding SiO₂/Al₂O₃ ratio of 3.5 (Fig. 5a), identical to the results of White and Barr (2010) from elsewhere in Meguma terrane. Samples with more than 65% SiO₂ when plotted on the chemical discrimination diagram of Herron (1988) are wacke to litharenite, whereas those with less than 65% SiO₂ are mainly shale to Fe-rich shale (Fig. 5b). On the chemical classification of sandstone diagram of Pettijohn *et al.* (1987), samples with more than 65% SiO₂ plot mainly in the litharenite field (Fig. 5c).

Metasandstone, siltstone, slate, and calc-silicate nodules were analyzed in each formation and plotted according to stratigraphic position against several chemical parameters (Figs. 6 and 7). The Taylors Head formation is typically low in CaO and MnO (Fig. 6a, b) and there is no difference between metasandstone and metasiltstone/slate. However, metasandstone samples with a carbonate matrix/cement are slightly higher in CaO with calc-silicate nodules having up to 23 wt. % CaO and no significant MnO (Fig. 6a, b). Fe₂O₃^T tends to be higher in the metasiltstone and slate samples than in metasandstone samples (Appendix A–D). The metasiltstone-rich Beaverbank formation is higher in CaO and MnO with the metasandstone

having the lowest concentrations and the metasiltstone and slate slightly higher (Appendix A, B). The coticule nodules and layers are significantly higher in MnO, CaO, and Fe₂O₃^T (Fig. 6a, b, c) but that correlation is not 1:1 as some metasiltstone samples with high CaO are low in MnO and Fe₂O₃^T. In contrast, all samples in the overlying Cunard formation display low CaO and MnO but Fe₂O₃^T remains high. Metasandstone and metasiltstone samples from the Bluestone formation are somewhat similar in CaO, MnO, and Fe₂O₃^T to those from the underlying Cunard formation; however, the calc-silicate nodules are significantly higher in CaO and only slightly higher in MnO and Fe₂O₃^T (Fig. 6a, b).

Total weight percent sulphur also varies with stratigraphic position and rock type, with median values of 0.04 in the Taylors Head formation, 0.32 in the Beaverbank formation, 1.29 in the Cunard formation, 0.17 in the Bluestone formation, and 0.01 in the granitoid rocks of the South Mountain Batholith (Fig. 7a; Appendix A–E). The higher values in the Beaverbank, Cunard, and Bluestone formations are attributed to abundant pyrrhotite. Some of the highest values (> 5 wt. %) are in hornfelsic samples from around the South Mountain Batholith. Typically there is a positive correlation between total sulphur and total metals (Cu + Pb + Zn) (e.g., Hammarstrom *et al.* 2003) but only the Cunard formation displays this trend (Fig. 7b). However, Pb, Zn, Cu, and As show no significant differences with stratigraphic position and all of the anomalous samples are located in the contact aureole of the South Mountain Batholith (Fig. 7c, d, e, f).

The chemical change at the contact between the Taylors Head and Beaverbank formations marks a dramatic and rapid change in the original seawater chemistry where conditions were favourable for deposition of Ca, Mn, Fe, and S. Under anoxic conditions Mn-oxide served as the oxidant, thereby leading to the eventual precipitation of manganese carbonate near the sediment-water contact (Graves and Zentilli 1988). These conditions are also favourable for sulphide mineral precipitation. The Beaverbank formation contains some of the highest total carbon values compared to the other formations (Table 1a).

The Beaverbank formation and equivalent Mosher's Island formation elsewhere in the Meguma terrane are also enriched in Pb, Zn, Cu, and As (Graves and Zentilli 1988); however, the Taylors Head, Cunard, and Bluestone formations are also locally enriched in these elements (e.g., White 2010b). In the HRM area this enrichment appears to be associated with contact metamorphic effects from the South Mountain Batholith as indicated by the increased presence of chalcopyrite, galena, sphalerite, and arsenopyrite in the contact aureole (Clarke *et al.* 2009).

Acid generation prediction

In Nova Scotia, the Sulphide Bearing Material Disposal Regulations state that rocks having sulphide sulphur contents equal to or greater than 0.4 weight % must be considered as hazardous ARD material. The portable XRF results, like the results from Acme Analytical Laboratories, are presented as

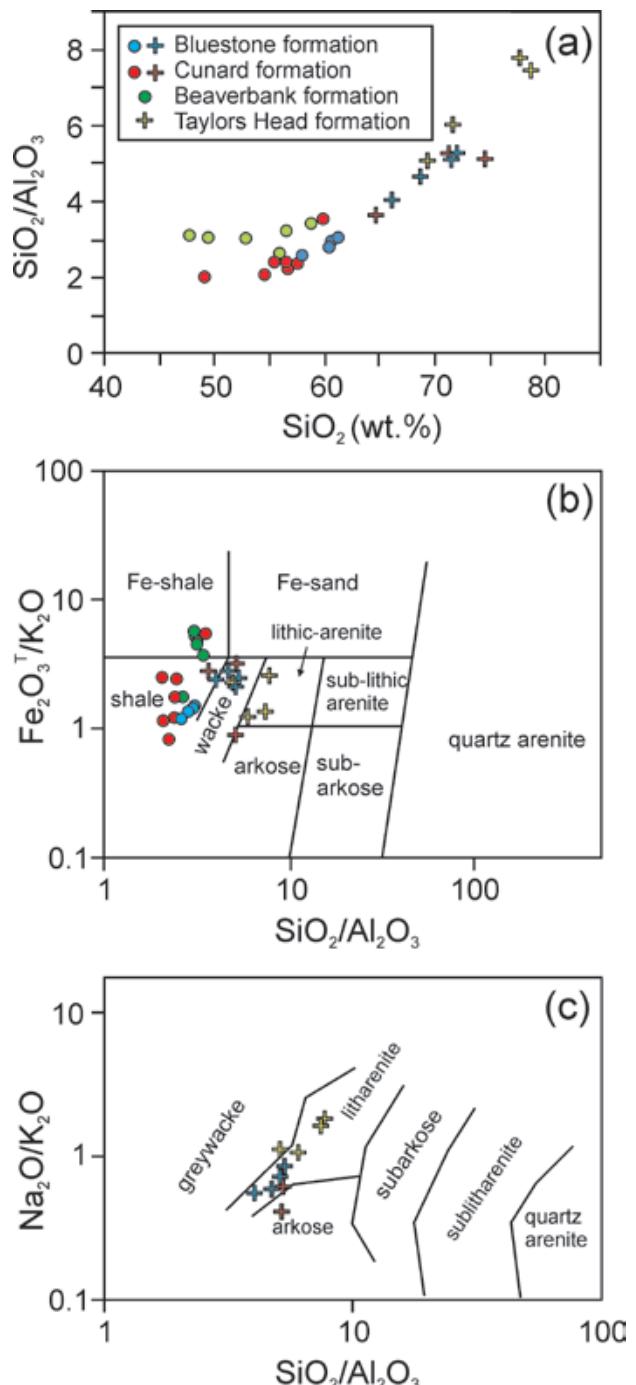

Fig. 5. (a) Plot of SiO₂ against SiO₂/Al₂O₃ where classification as sandstone (plus symbols) or siltstone/mudstone (circles) is based on petrographic study. (b) Chemical classification using Fe₂O₃^T/K₂O versus SiO₂/Al₂O₃. Fields are from Herron (1988). (c) Chemical classification using Na₂O/K₂O versus SiO₂/Al₂O₃. Fields are from Pettijohn *et al.* (1987).

total weight % sulphur which, based on the data in Table 2, is about 17% higher than total sulphide sulphur, except in samples from the Cunard formation where the ratio is almost 1:1 (Table 2). Although assigning all sulphur to sulphides is per-

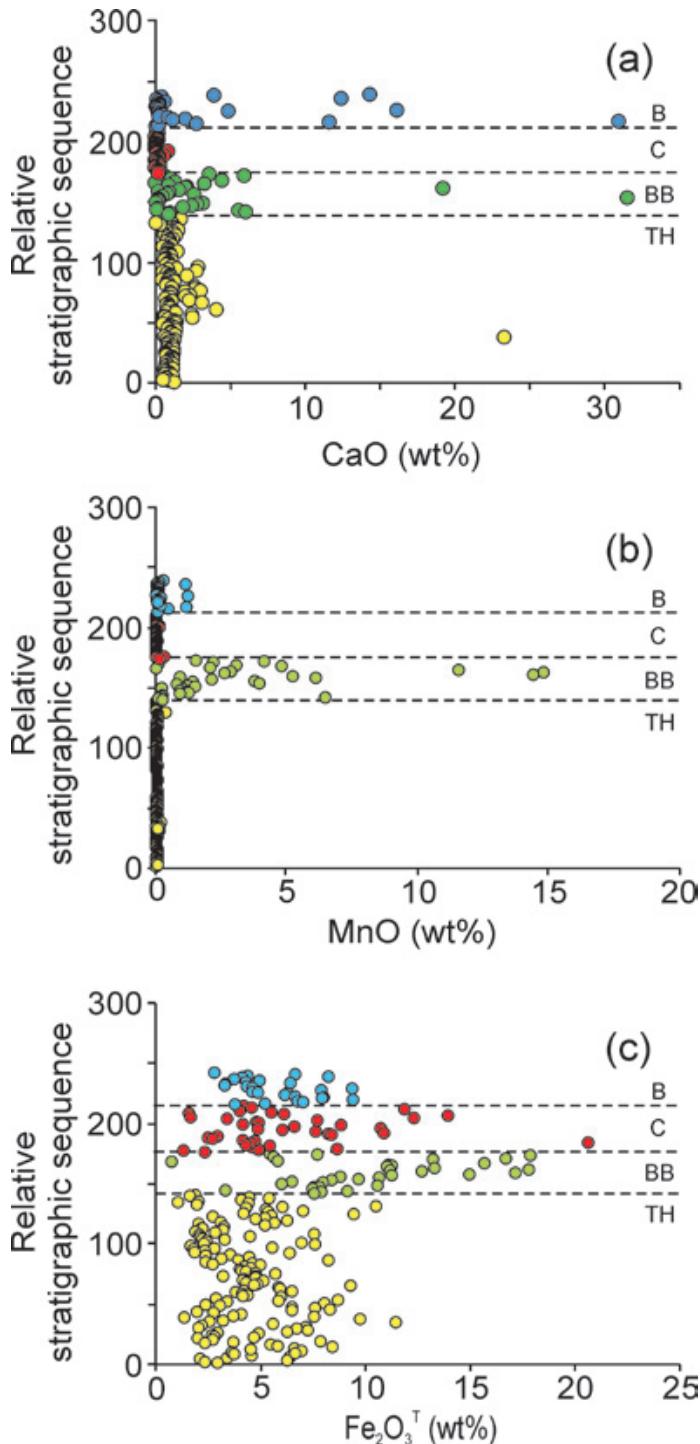

Fig. 6. Plots of selected chemical parameters against relative stratigraphic position: (a) CaO, (b) MnO, and (c) Fe_2O_3^T in the Goldenville and Halifax groups. Abbreviations: B = Bluestone formation; C = Cunard formation; BB = Beaverbank formation; TH = Taylors Head formation. Symbols are as in Fig. 3.

haps overly conservative as it ignores contributions from non-acid generating phases (e.g., sulphates and organic matter), the total weight % sulphur and total sulphide sulphur can be

considered interchangeable; hence, a rock with total sulphur content equal to or greater than 0.47 can be considered hazardous (Fig. 7a). However, this parameter does not take into account the possible neutralizing capacities of minerals in the rock (Weber *et al.* 2005) or the varying reactivities of different sulphide minerals.

The most important acid neutralizing minerals in the Goldenville and Halifax groups are calcite and dolomite and, to a much lesser extent, rhodochrosite and ankerite. The neutralizing power of feldspar varies considerably, depending on its composition. Altered (i.e., sericitized) feldspar has much less neutralizing power than its unaltered or carbonatized equivalents. Potassium-rich feldspar (orthoclase/microcline) and Na-rich plagioclase (albite) have less neutralizing power than the more Ca-rich plagioclase (anorthite). The metasandstone in the lower grade regional metamorphic rocks typically contains albitic plagioclase; however, in the contact metamorphic aureole plagioclase (10–40 modal %) is typically more Ca-rich (oligoclase to andesine) which adds to the neutralizing power. Minerals containing Mg (biotite and chlorite) also contribute to buffering ARD, but play a minor role (Weber *et al.* 2005). In the Goldenville and Halifax groups it is likely that the abundance of plagioclase and its alteration products, along with carbonate minerals, largely determine the neutralizing power in high sulphur samples. In comparison, the granitoid rocks of the SMB have total sulphur less than 0.20 weight % and pose no apparent ARD risk (Fig. 8; Appendix E).

The potential for acid generation is dependent on the ratio of acid-producing potential (APP) to acid-consuming ability (ACA). Following the legally binding British Columbia Research Initial Test the neutralizing power of 23 samples has been calculated (Table 2) and plotted (Fig. 9a). A 1:1 ratio (acid/base) is plotted and assumes that the tested samples that plot below this ratio are net acid consumers (e.g., Schoeffer and Clawson 1996). However, Lawrence and Scheske (1997) noted that different mineral groups have different relative reactivities (i.e., carbonate minerals react faster than feldspar minerals), and hence the control on neutralization varies with mineralogy and a more suitable value for the neutralizing potential is 0.54. Because it is difficult to predict the short- and long-term acid generation potential of a rock unit a “zone of uncertainty” was defined between the 1:1 and 1:2 gradient lines (Fig. 9a, b) (Bell and Bullock 1996; Campbell *et al.* 2001).

Total S wt% versus CaO wt% can be considered equivalent to APP/ACA in a theoretical sense (e.g., Downing and Madejsky 1997) and it has been shown that data from the portable XRF is comparable to Acme Analytical Laboratories and British Columbia Research Initial Test results (Fig. 3). Hence, a plot of total S wt. % versus CaO wt. % for data collected from the portable XRF can be used with a significant degree of confidence as a first approximation for acid generating potential of the rock.

Figure 9b shows a wide distribution of sample populations which indicates that three units are potentially acid producers (Bluestone, Cunard, and Beaverbank formations), and two units are non-acid producing (Taylors Head formation and South Mountain Batholith). About 97% of the samples col-

lected from the Cunard formation are potential acid producers with an APP/ACA and S/CaO ratios of >1.0 (Fig. 9a, b) and a high median total sulphur content of 1.31 %. About 3% of the samples are non-acid producers. In comparison, 26 % of the samples in the stratigraphically higher Bluestone formation and

24 % of the samples from the underlying Beaverbank formation are potential acid producers with average total sulphur of 0.30% and 0.90%, respectively. However, about half (50–55%) of the samples from these two formations lie in the zone of uncertainty and hence can be acid producers under the right

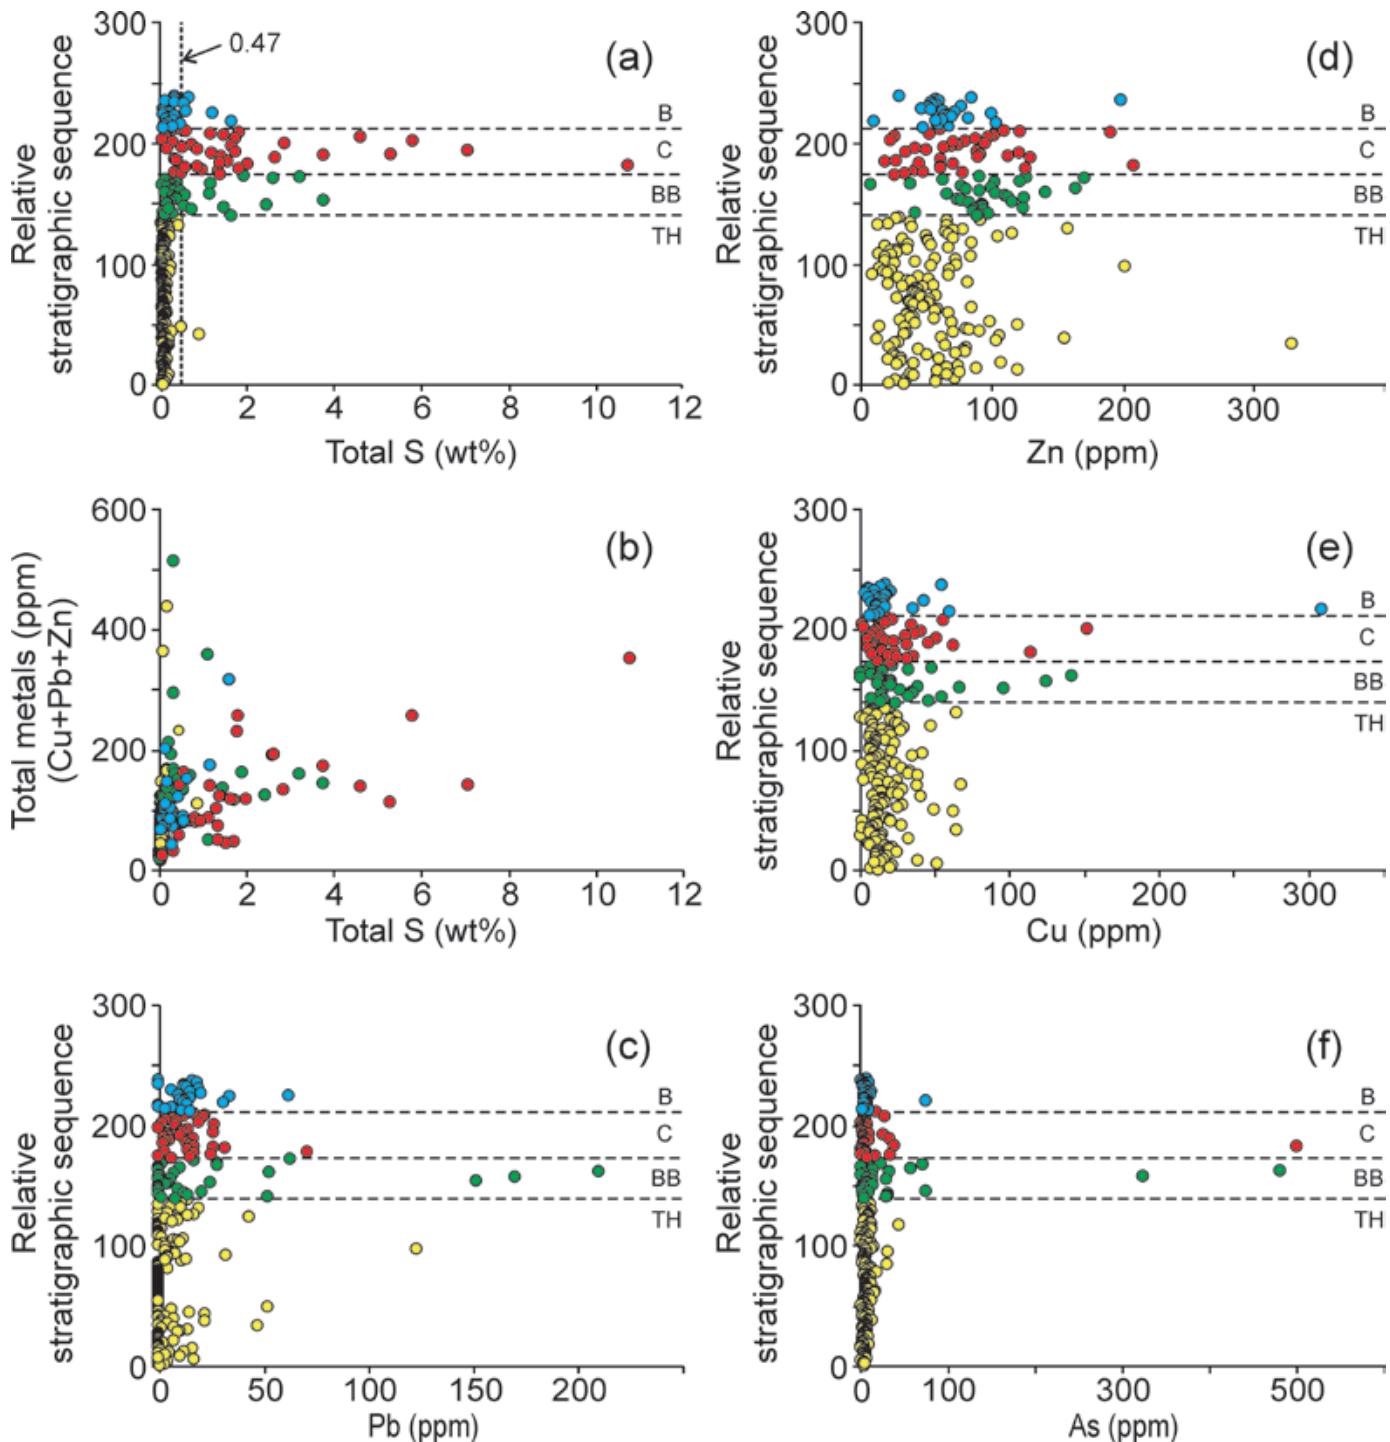

Fig. 7. Plots of selected chemical parameters against relative stratigraphic position: (a) S, (c) Pb, (d) Zn, (e) Cu, and (f) As, and (b) plot of total S against total metals in the Goldenville and Halifax groups. Abbreviations: B = Bluestone formation; C = Cunard formation; BB = Beaverbank formation; TH = Taylors Head formation. Symbols are as in Fig. 3.

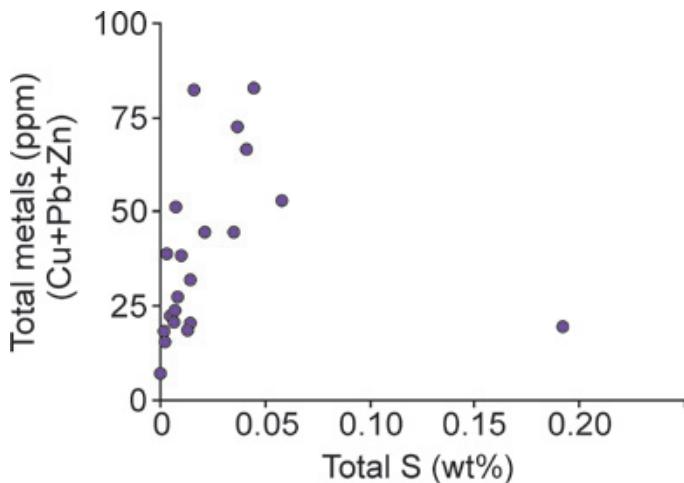

Fig. 8. Plot of total S against total metals in the South Mountain Batholith.

conditions. The high sulphur percentage and acid producing potential in the Bluestone, Cunard, and Beaverbank formations is consistent with major basin-wide stagnation in which anoxic conditions existed during the depositional history of these formations (Waldron 1987; Graves and Zentilli 1988). The high proportion of acid-producing rocks in the Cunard formation can be directly linked to the low acid-buffering CaO content (median = 0.09 wt. %) compared to the Bluestone and Beaverbank formations (median = 0.39 and 1.29 wt. %, respectively) (Appendix A–C).

About 99% of the samples from the Taylors Head formation are non-acid producing (Fig. 9b) and have a low total sulphur content (median = 0.04 wt. %) (Appendix D). One sample (D12-W09-101) that is a potential acid producer has low total sulphur (0.023 wt. %) and low CaO (0.01 wt. %) and is one of two samples that is classified as quartz arenite (Fig. 4b) and hence is not likely to produce acid due to the high quartz content. The other sample classified as quartz arenite (D12-W07-015) is a spotted metasiltstone which contains 0.86 wt. % sulphur (Appendix D). It is from a thin (< 20 cm thick) bed within a massive metasandstone bed and, although this sample has the potential to produce acid, the effects would likely be diluted by the surrounding non-acid producing metasandstone.

About 95% of the granitoid samples from the South Mountain Batholith are non-acid producing (Fig. 9b) and have the lowest average total sulphur content (0.017 wt. %) of all the units sampled (Appendix E). One sample (CW-270B) plots in the zone of uncertainty and has a total sulphur content of 0.859 wt. %. It has an elevated sulphur percentage compared to the other granitoid samples because it is a pyrite-bearing aplite-pegmatite dyke cutting the South Mountain Batholith. Because this is a minor unit the acid-producing potential is considered as low.

A useful application of susceptibility measurements is to determine the presence of sulphide-bearing minerals in outcrop. High magnetic susceptibility measurements are indicative of the presence of ferromagnetic and paramagnetic minerals

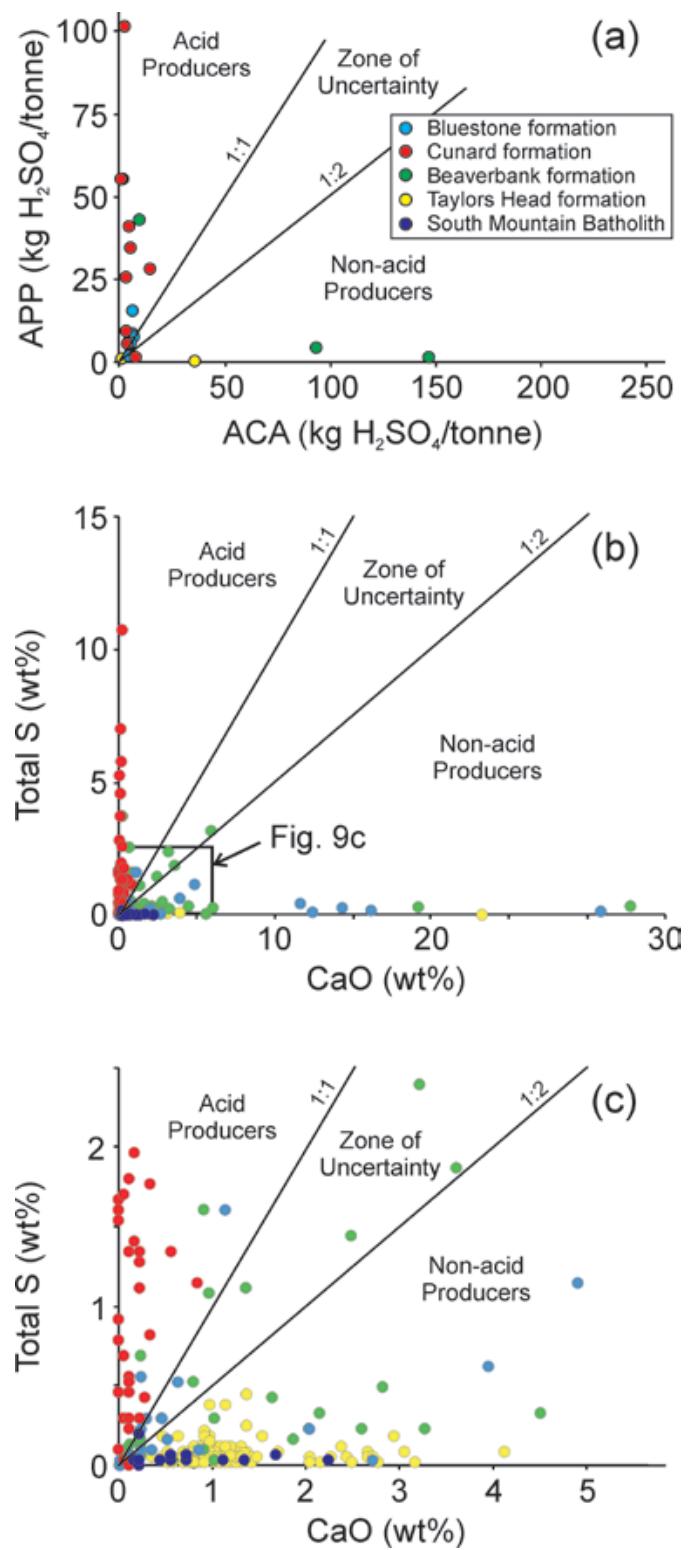

Fig. 9. (a) Plot of acid-producing potential (APP) against acid-consuming ability (ACA) using results from the British Columbia Research Initial Test. (b) Plot of total S against CaO using results from the portable XRF. Area of Fig 9c is shown in box. (c) Close-up of data in box shown at origin in Fig. 9b.

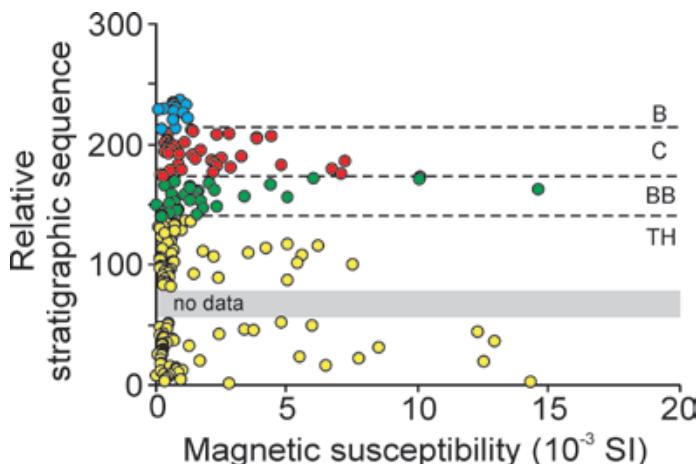

Fig. 10. Plot of magnetic susceptibility against stratigraphic position in the Goldenville and Halifax groups. Abbreviations: B = Bluestone formation; C = Cunard formation; BB = Beaverbank formation; TH = Taylors Head formation. Symbols are as in Fig. 3.

(e.g., King 1997; Howells and Fox 1998; Fitzgerald and Goodwin 2005). In the Taylors Head formation the high magnetic susceptibility measurements are due to the presence of magnetite and to a lesser degree ilmenite. In contrast, the high readings in the Beaverbank, Cunard, and Bluestone formations are due to the presence of pyrite in the lower metamorphic grade rocks and pyrrhotite in the higher metamorphic grade contact aureole of the South Mountain Batholith (Fig. 10). The susceptibility data aid in delineating problematic, potentially acid-producing units before excavation takes place. However, detailed petrographic analysis is required to determine the character of the magnetic mineral. As shown in Figure 10, the metasandstone in the Taylors Head formation yields high magnetic susceptibility measurements but based on other data this rock type is low risk in terms of producing acid rock drainage.

CONCLUSIONS

Rock samples lacking abundant sulphide minerals were purposely collected and analyzed to represent the average lithogeochemistry and ARD potential for units in the metropolitan area of HRM. This study showed that many of these unmineralized rocks have the potential to produce acid. The main acid producers are slate, metasiltstone, and metasandstone of the Beaverbank, Cunard, and Bluestone formations, with the Cunard formation having the highest acid-producing potential. The older, dominantly metasandstone-rich Taylors Head formation, as well as the granitoid rocks of the South Mountain Batholith, are non-acid producing. However, the acid-producing potential is greatly increased in contact metamorphosed rocks, especially in the Cunard formation, adjacent to the South Mountain Batholith.

It has been demonstrated that ARD buffering behaviour is

based on the bulk rock chemistry and modal mineralogy of the rock. Hence, knowledge of rock type, alteration characteristics, and depositional environment is important in understanding and predicting the ARD buffering capacity. This study demonstrates that a detailed geological map and petrographic study coupled with lithogeochemical data are needed in order to better ascertain acid rock drainage potential.

Whole rock and sulphur analyses obtained by the portable XRF are a cost-effective way, compared to the acid-base accounting (ABA) test, to estimate the APP/ACA of rocks to provide an early warning of possible ARD problems. Although this approach is not intended as a substitute for the legally mandated ABA test procedure, it could facilitate timely and cost-effective management and mitigation of possible ARD throughout the Goldenville and Halifax groups and in geologically similar areas world-wide.

ACKNOWLEDGEMENTS

We thank Rebecca Jamieson and John Waldron for their insights into the metamorphic history and stratigraphy of the Bluestone formation and summer students Duncan McLeish, Janice Bell, Alex Kaul, and Kara-Lynn Scallion who contributed to the mapping in HRM. We thank Nova Scotia Department of Natural Resources editor Doug MacDonald, internal reviewer Garth Prime, Atlantic Geology reviewers Drs. Michael Parsons and Donald Fox, and Editor Dr. Sandra Barr for their helpful comments, which led to substantial improvements in the manuscript and their efforts are greatly appreciated. Financial support for this project was provided by the operating budget of the Nova Scotia Department of Natural Resources to the authors. This paper is published with the permission of the Director, Nova Scotia Department of Natural Resources.

Notes: Abbreviations: SO = stratigraphic order from oldest (lower number) to youngest (higher number); Mag = magnetic susceptibility in 1×10^{-3} SI units; n.d. = not determined; b.d.l. = below detection limit; * Zone 20. Samples with PPP, PC, and WL prefixes are from Dr. R.A. Iameison's (Dalhousie University) rock collection.
